

The schedule, and the two things it can be checked against

(a) is the layer's external check and it runs BACKWARDS: two schedules a trial reported as not differing imply the alpha/beta at which they are equivalent, and that value is compared against estimates derived from other data (shaded). Prostate lands inside its band; breast crosses at 0.70 Gy, far below any plausible tissue, because its shorter arm delivers less total dose and was still not inferior - a statement about what EQD2 leaves out. (b) and (c) are DIRECTION-only: the late-tissue alpha/beta is a convention and the reoxygenation half-life is a free parameter no dataset here constrains.
