

Two effects push a chemotherapy kill to the rim, and they have opposite remedies

A drug has to REACH a cell, and a cycle-specific agent has to find it CYCLING - and both fail in the same place, so an observed rim-biased kill is ambiguous between 'the drug did not get there' and 'those cells were not dividing'. The two have opposite remedies, better delivery against cell-cycle recruitment, so telling them apart is worth more than either number alone; the point model has neither term. (a) is the control that makes the rest terms rather than artifacts of the zoning. (b) says delivery dominates ON THESE PARAMETERS - the penetration length was chosen, not measured, and a longer one shifts the balance. (c) is the part better delivery cannot fix, and the check that the cycle arm is really the cell cycle: an alkylator damages DNA whatever the cell is doing and keeps most of its core kill, while the phase-specific agents lose most of theirs.
