

Multiplying the barrier fractions is right only when the barriers are independent

`adoptive::delivery\_efficiency` multiplies trafficking, infiltration and activation, and the arm multiplies by the antigen fraction on top. That is exactly right when the terms are INDEPENDENT - and two of them are not in a tumour, because infiltration is a property of WHERE a cell sits and antigen of the CELL. The spatial run replaces the infiltration SCALAR with a depth field of the same mean, so the two models differ in distribution and nothing else. (b) is the control and the finding at once: at zero correlation they agree to 0.6%, which is what makes the rest a finding rather than a bug - the first version of this measurement double-counted the infiltration barrier and its control failed at every correlation. The effect stops growing at the positive extreme because the per-cell antigen probability saturates at 1, which is marked rather than smoothed. This is not a measurement of any real antigen-depth correlation; it shows the answer depends on one, and by how much.
