

Checkpoint blockade cannot start a response, and a fold-change cannot say whether one matters

`checkpoint::residual\_brake` returns a MULTIPLIER, and a multiplier has no denominator: 'blockade raises immune killing 2.5-fold' is true and does not say 2.5 times WHAT. (a) and (b) are the SAME runs. The fold-change is identical for both active treatments, because a multiplier does not know what it multiplies - so the quantity the point model reports is exactly the one that cannot tell the two cases apart. The share differs 31-fold. The untreated arm gets nothing at ANY blockade strength, which is the cold-tumour problem stated where it can be checked. (c) is the warning: the treatment producing four times the danger signal has the SMALLER immune share, because it already killed almost everything directly - so ranking partners by immunogenic signal gets this backwards. Absolute immune contribution in this engine is small and known to be: the manuscript records the immune ratio collapsing about 104:1 to 4:1 in three dimensions.
