

Oncolytic spread is a threshold, and a closed-form front speed cannot express one

``oncolytic::front_speed`` is the Fisher-KPP speed $2\sqrt{D*r}$ - the speed of a front in a HOMOGENEOUS medium - so it returns a positive number whenever replication beats clearance and has no term for how much of the tumour the virus can enter. On a lattice that is false, and the failure is sharp: below a site-percolation threshold there is no connected path of enterable cells and no dose or duration gets the infection across. The measured threshold at certain transmission brackets 0.0976, the 26-neighbour site-percolation constant for the neighbourhood this grid uses - a number from computational physics that nothing here was fitted to, and which excludes the 6-neighbour value of 0.3116. Crosses mark runs where no enterable cell existed near the seed at all: a failure to START, which is a different claim from a failure to cross and is marked rather than drawn as a zero. This says the spread RULE behaves like site percolation on its own lattice; it is not evidence that tumours percolate.
